Electric power steering apparatus.

The invention provides an electric power steering apparatus, in which one of a pair of switching elements (Q₁,(Q₂),(Q₃),(Q₃), that has been PWM controlled is turned off and the other switching elements.

ment is PWM controlled instead when a steering wheel is returning to its neutral position, thereby allowing the steering wheel to return smoothly and preventing a control hunting.

FIG. 5

Rank Xerox (UK) Business Services

BACKGROUND OF THE INVENTION

Field of the Invention

The present invention relates to an electric power steering apparatus, and more particularly it relates to improvement in motor driving while a steering wheel is returning to its initial position.

Description of Related Art

In an electric power steering apparatus widely used these days, a motor is driven by a current value corresponding to detected steering torque, and the thus obtained driving force of the motor is transferred to a steering mechanism so as to assist the steering power.

FIG. 1 is a circuit diagram showing the configuration of a motor control circuit in a conventional electric power steering apparatus. FETs Q1, Q2, Q3 and Q4 form a bridge circuit between a power supply E and a ground terminal. A motor M and a resistance R for detecting a motor driving current are connected in series so as to bridge the contact hetween the FETs Q1 and Q3 connected in series and the contact between the FETs Q2 and Q4 also connected in series. The voltages at both ends of the resistance R for detecting a motor driving current are respectively inputted to the non-inverted input terminal and the inverted input terminal of a differential amplifler 4, which outputs a differential output generated in accordance with the inputted voltages as a signal la being equivalent to the motor driving current. Further, the FETs Q1, Q2, Q3 and Q4 contain free wheeling diodes D1, D2, D3 and De connected thereto in parallel, respectively.

A value of steering torque supplied to a steering wheel (not shown) and detected by a torque sensor 5 is inputted to a signal processor 3, which outputs, in accordance with the detected torque, a signal Is being equivalent to a target motor current (i.e., a target value of a motor current) to the noninverted input terminal of a differential amplifier 1. To the inverted input terminal of the differential amplifier 1 is inputted the signal In being equivalent to the aforementioned motor driving current. The differential amplifier 1 outputs to an FET driving circuit 2 a difference between these inputted values as a signal V₁ being equivalent to a target motor voltage required for supplying the target motor current to the motor M. In the FET driving circuit 2, a motor driving voltage V_N is generated from the signal V1 being equivalent to the target motor voltage. By using a duty ratio in accordance with the magnitude of the absolute value of the motor driving voltage V_N, and also in accordance with the polarity of the motor driving voltage V_N, the FET driving circuit 2 turns on the FET Q3 and simultaneously performs a pulse width modulation control (hereinafter referred to as PWM control) on the FET Ω_2 , or turns on the FET Ω_3 and simultaneously performs the PWM control on the FET Ω_4 . thereby driving the motor M in the clockwise or counterclockwise direction.

While a steering wheel (not shown) is returning to its neutral position, however, the driving direction of the motor M (i.e., the direction in which the motor is to be rotated) in accordance with the steering torque detected by the torque sensor 5 is different from the actual rotation direction of the motor M. Accordingly, a generated current caused by the rotation of the motor M flows through the circuit, resulting in causing a control hunting. As a result, not only an abnormally loud noise is made in the motor M but also a braking force in the reverse direction of the rotation direction of the steering wheel is generated, thereby proventing the steering wheel from returning to its neutral position smoothly.

Such a phenomenon will now be described in more detail. In returning the steering wheel to its neutral position, if the motor M is rotated in. for example, the counterclockwise direction while driving in the clockwise direction, the FET Q2 is PWM controlled and the FET Q₃ is turned on, FIG. 2 is a circuit diagram illustrating the operation of the bridge circuit in a general motor control circuit. As is shown in FIG. 2, when the PWM controlled FET Q2 is on, a PWM controlled current flows through the FETs Q2 and Q3 as shown with a solid line arrow 6. When the PWM controlled FET Q2 is turned off, a generated current caused by the rotation of the motor M and a regenerated current caused by the inductance of the motor M both in the direction shown with a broken line arrow 7 flow through the FET Q2 and the diode D4. When the generated current is increased, the differential output of the differential amplifier 4, i.e., the signal Id being equivalent to the detected value of the motor driving current, is increased to exceed the signal I₁ being equivalent to the target motor current (i.e., the non-inverted input has a larger absolute value than the inverted input). Then, the polarity of the differential output of the differential amplifier 1, i.e., the signal V₁ indicating the target motor voltage. becomes reverse of that of the signal I1 being equivalent to the target motor current. When the notarity of the signal V₁ indicating the target motor voltage becomes reverse, the FET driving circuit 2 makes the motor driving voltage V_N zero, thereby turning off all the FETs including the FETs Q2 and Q3. Accordingly, no current flows through the resistance R, and the differential output of the differential amplifier 4, i.e., the signal Id being equivalent to the detected value of the motor driving current, becomes zero. As a result, the polarity of the

differential output of the differential amplifier 1, i.e., the signal V_1 being equivalent to the target motor voltage, regains its original polarity.

When the signal V1 being equivalent to the target motor voltage regains the original polarity. the FET driving circuit 2 generates the motor driving voltage VN corresponding to the signal V1 being equivalent to the target motor voltage, and performs the PWM control on the FET Q2 and turns on the FET Q₃ again. When the FET Q₂ is PWM controlled and the FET Q3 is turned on, a PWM controlled current flows through the FETs Q2 and Q₃, and a generated current caused by the rotation of the motor M flows through the FET Q3 and the diode D4 again. The generated current is in- . 15 creased, thereby increasing the differential output of the differential amplifier 4, i.e., the signal Id being equivalent to the detected value of the motor driving current to exceed the signal Is being equivalent to the target motor current. That is to say, the inverted input has a larger absolute value than the non-inverted input. Then, the polarity of the differential output of the differential amplifier 1, i.e., the signal V₁ being equivalent to the target motor voltage, becomes reverse again. In this manner. such a process is repeated, resulting in disadvantageously causing the control hunting and making an abnormal noise in the motor M.

Next, a motor lock check circuit will be described. FIG. 3 is a block diagram showing the configuration in the major part of the motor lock check circuit in the conventional electric power steering apparatus. The motor lock check is an operation to check whether or not the motor in the electric power steering apparatus normally works (i.e., whether or not the motor is locked) when an ignition switch is turned on. FETs Q1, Q2, Q3 and Q4 form a bridge circuit, and a motor M and a resistance R for detecting a motor driving current are connected in series so as to bridge the contact between the FETs Q1 and Q3 connected in series and the contact between the FETs Q2 and Q4 connected in series. The FETs Q1, Q2, Q3 and Q4 are connected with free wheeling diodes D1, D2, D3 and D4 in parallel, respectively. The bridge circuit, a fail safe relay 24 and a power supply B are connected in series.

After an ignition switch (not shown) is turned on, the fall self relay 24 is turned on by a controller (not shown). In an off condition of an electromagnetic clutch (not shown) for transferring the driving force of the motor M to a steering assisting mechanism, a signal processor 23 turns on, for example, the FETs Q and Qx via an FET driving circuit 20, and drives the motor M for a predetermined period of time by a driving current flowing in the direction shown with a solid line arrow 25. Then, the signal processor 23 turns off all the FETs

including the FETs Ω_t and Ω_t , and allows the motor to trate by the inertial force. A motor terminal voltage detecting circuit 22 detects a generated voltage caused by this rotation of the motor M_t . Then, the signal processor 23 outputs a signal for braking the motor M_t to the FET driving circuit 20 before the electromagnetic clutten is turned on. The FET driving circuit 20 turns on the FET Ω_t in response to the signal for braking the motor M_t and the motor M_t is stopped by a regenerated current that is generated by the generated voltage caused by the inertial rotation of the motor M_t and flows through the free wheeling clinde D_t and the FET Ω_t in the direction shown with a broken line arrow 26

FIG. 4 is a timing chart showing the variation in the motor current during the motor lock check. In this timing chart, T₁ indicates a driving time of the motor M₁, when a driving current flows as shown with the solid line arrow 25; T₂ indicates a time required for detecting a generated voltage caused by the inertial rotation of the motor M₁, when no current flows through the bridge circuit because all the FETs are off; and T₂ indicates a braking time of the motor M₁, when a regenerated current flows in the direction shown with the broken line arrow 26.

In this manner, in a conventional motor lock check circuit, a generated voltage caused by the rotation of the motor M is detected by the motor terminal voltage detecting circuit 22, which detection requires the time T₂.

SUMMARY OF THE INVENTION

The present invention is devised to solve the above-mentioned problems, and the objective of the invention is providing an electric power steering apparatus in which a steering wheel can be smoothly returned to its neutral position and no control hunting is caused.

The electric power stooring apparatus of this invention comprises a bridge circuit including a motor and two pairs of switching elements provided for driving the motor in the clockwise direction and in the counterclockwise direction, respectively, decision means for deciding whether or not said steering wheel is being roturned to its neutral position, and means for performing PWM control on one switching element of one pair of the two pairs of switching element of one pair of the two pairs of switching element of need and turning off the other switching element of that particular pair of the switching elements when the decision means decides that the steering wheel is being returned to its neutral position.

Accordingly, while the steering wheel is being returned to its neutral position, a generated current caused by the rotation of the motor flows in according to the control of the motor flows in according to the control of the motor flows in according to the control of the cont

15

dance with a duty ratio of the PWM control. Therelore, the motor driving current never becomes zero, thereby preventing a control hunting and allowing the steering wheel a smooth braking force.

In the electric power steering apparatus of the invention, said decision means includes a resistance connected with said motor in series at a bridging portion in said bridge circuit, a differential amplifier for obtaining a difference between a motor driving current detected at said resistance and a target value of the motor driving current in accordance with the torque supplied to said steering wheel, means for deciding whether or not the polarities of the target value of said motor driving current and a differential output of said differential amplifier are different, and means for detecting the change of the polarity of said differential output. When the means for deciding whether said polarities are different decides that the polarities are different and the means for detecting the change decides that said polarity is changed, the decision means decides that said steering wheel is being returned to its neutral position.

Accordingly, when said decision means decides that the steering wheel is being returned, one of the switching elements that has been PWM controlled is turned off, and the other of the switching elements is PWM controlled instead. As a result, a generated current caused by the rotation of the motor is allowed to flow in accordance with a duty ratio of the PWM control. Therefore, the motor driving current never becomes zero, thereby preventing a control hunting and allowing the steering wheel a smooth braking force.

The above and further objects and features of the invention will more fully be apparent from the following detailed description with accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a circuit diagram showing the configuration of a motor control circuit in a conventional electric power steering apparatus;

FIG. 2 illustrates the operation of a bridge circuit

in the usual motor control circuit; FIG. 3 is a block diagram showing the configuration in the major part of a motor lock check circuit in the conventional electric power steer-

ing apparatus;
FIG. 4 is a timing chart for the operation of the motor lock check circuit of FIG. 3:

FIG. 5 is a circuit diagram of the configuration in the major part of a motor control circuit in an electric power steering apparatus according to an embodiment of the invention;

FIG. 6 illustrates the operation of the motor control circuit of FIG. 5;

FIG. 7 is a flow chart for the operation of the motor control circuit of FIG. 5;

FIG. 9 is a block diagram of the configuration in the major part of a motor lock check circuit in the present electric power steering apparatus;

FIG. 10 is a timing chart for the operation of the motor lock check circuit of FIG. 9; and

FIG. 11 is a flow chart for the operation of the motor lock check circuit of FIG. 9.

DESCRIPTION OF THE PREFERRED EMBODI-MENTS

The present invention will now be described referring to the accompanying drawings illustrating the embodiments thereof.

FIG. 5 is a circuit diagram of the configuration in the major part of a motor control circuit in an electric power steering apparatus according to one embodiment of the invention, and FIG. 6 Illustrates the operation of a bridge circuit in the motor control circuit. FETs Q1, Q2, Q3 and Q4 form the bridge circuit between a power supply E and a ground terminal, A motor M and a resistance R for detecting a motor driving current are connected in series so as to bridge the contact between the FETs Q1 and Q3 connected in series and the contact between the FETs Qo and Qu connectedin series. The FETs Q1, Q2, Q3 and Q4 are connected with free wheeling diodes D1, D2, D3 and D4 in parallel. respectively. Voltages at both ends of the resistance R for detecting the motor driving current are inputted to the non-inverted input terminal and the inverted input terminal of a differential amplifier 4. which sends the differential output to the inverted Input terminal of a differential amplifier 1 described below as a signal Id being equivalent to a detected value of the motor driving current.

The value of steering torque supplied to a steering wheel (not shown) and detected by a torque sensor 5 is inputted to a signal processor 11, which outputs, in accordance with the detected torque, a signal Is being equivalent to a target motor current (i.e., a target value of the motor current) to the non-inverted input terminal of the differential amplifier 1. The inverted input terminal of the differential amplifier 1 receives the signal In being equivalent to the detected value of the motor driving current as described above, and hence, the differential amplifier 1 outputs a difference between these inputted values to an FET driving circuit 10 as a signal V₁ being equivalent to a target motor voltage required for supplying the target motor current to the motor M.

In the FET driving circuit 10, the signal V₁ being equivalent to the target motor voltage is used

as a current motor driving voltage V_u in the current sampling cycle. By using a duty ratio corresponding to the magnitude of the absolute value of the motor driving voltage V_u, and also in accordance with the polarity of the motor driving voltage V_u, the FET driving circuit 10 controls the driving of the motor M in the clockwise or the counterclockwise direction. This control is performed by, for example, turning on the FET Q_a and simultaneously PWM controlling the FET Q_c or by turning on the FET Q. and simultaneously PWM controlling the FET Q_c.

The operation of the electric power steering apparatus having the aforementioned motor control circuit will be described referring to flow charts shown in FIGs. 7 and 8.

The value of the steering torque detected by the torque sensor 5 is inputted to the signal processor 11, which outputs the signal I₁ being equivalent to the target motor current in accordance with the detected torque to the non-inverted input terminal of the differential amplifier 1. The inverted input terminal of the differential amplifier 2 traceves, as described above, the signal I₄ being equivalent to the detected value of the motor driving current, and herefore, the differential amplifier 1 outputs a difference between these inputted values to the FET driving circuit 10 and the signal processor 11 as the signal V, being equivalent to the target motor voltage.

The signal processor 11 compares the polarity of the signal I1 being equivalent to the target motor current with that of the target motor voltage (step S50). When their polarities are matched, that Is. when the driving force of the motor is insufficient, the FET driving circuit 10 uses the signal V1 being equivalent to the target motor voltage as the current motor driving voltage VM (step S51). When the current motor driving voltage V_N is not 0 (step \$52), the FET driving circuit 10 checks the polarity of the motor driving voltage V_N (step S53). When the polarity corresponds to the clockwise driving of the motor M, for example, the FETs Q1 and Q4 are turned off (step S54), and the FET Q3 is turned on (step S55). Simultaneously, the FET Q2 is PWM controlled at a duty ratio in accordance with the current motor driving voltage V_N (step S56). In this case, while the PWM controlled FET Q2 is on, a motor driving current in the direction as shown with a solid line arrow 6 in FIG. 2 flows through the FETs Q2 and Q3 in accordance with the duty ratio of the PWM control. While the PWM controlled FET Q2 is off, a generated current caused by the rotation of the motor M and a regenerated current caused by the inductance of the motor M both in the direction as shown with a broken line arrow 7 in FIG. 2 flows through the FET Q3 and the diode D4.

When the polarity of the current motor driving voltage V_N corresponds to the counterclockwise driving of the motor M. for example, the FETS Q_0 and Q_0 are turned off (step S71), and the FET Q_1 is turned on (step S72). Simultaneously, the IST Q_1 is PWM controlled at a duty ratio in accordance with the current motor driving voltage V_N (step) S73). In this case, a motor driving current flows through the FETS Q_1 and Q_2 in accordance with the duty ratio of the PWM control.

When the current motor driving voltage V_N is 0 (step S52), that is, when the steering torque is 0, and hence, the signal I, being equivalent to the target current is also 0, the FET driving clrcuit 10 turns off the FETs Q₁, Q₂, Q₃ and Q₄ (step S70). In this case, no current flows through the motor M.

The signal processor 11 compares the polarity of the signal I₁ being equivalent to the target motor current and that of the signal V₁ being equivalent to the target motor voltage (step SS0). When their polarities are not matched, the signal processor 11 compares the polarity of the signal V₁ being equivalent to the target motor voltage and that of a previous motor driving voltage V₂ In the previous sampling cycle of the signal processor 11 (step SS6).

When the polarities of the signal V₁ being equivalent to the target motor vollage and the motor driving voltage V₂ in the previous sampling cycle are not matched, the FET driving circuit 10 inverts the signal V₁ being equivalent to the target motor voltage (step S60), and the obtained inverted signal V₁ is used as the current driving voltage V₃ (step S61).

When the current motor driving voltage V_N is not 0 (step S62), that is, when the steering wheel is returning to its neutral position, the FET driving circuit 10 checks the polarity of the motor driving voltage V_N (step S63). When the polarity corresponds to the clockwise driving of the motor M, for example, the FETs Q1 and Q4 are turned off (step S64), and the FET Q2 is also turned off (step S65). Simultaneously, the FET Q3 is PWM controlled at a duty ratio in accordance with the current motor driving voltage V_N (step S66). In this case, a generated current of the motor M flows in the direction as shown with a solid line arrow 8 in FIG. 6 through the FET Q3 and the diode D4. The returning steering wheel is braked by merely a force generated from the PWM controlled generated current of the motor M. As a result, the steering wheel can be returned smoothly.

When the polarity of the current motor driving voltage V_{N} corresponds to the counterclockwise driving of the motor M, for example, the FETs Q_{2} and Q_{3} are turned off (step S67), and the FET Q_{1} is also turned off (step S68). Simultaneously, the FET Q_{1} is PWM controlled at a duty ratio in

accordance with the current motor driving voltage (A, (step) 890). In this case, a generated current of the motor M flows in the reverse direction of that shown with the solid line arrow 8 in FIG. 8 through the FET Q, and the diode D₃, and the returning steering wheel is braked by merely a force generated by the PVM controlled generated current of the motor M. As a result, the steering wheel can be returned smoothly.

When the current motor driving voltage $V_{\rm s}$ is 0 (step S62), that is, for example, the driving force of the motor M is neither too much nor too little, the FET driving circuit 10 turns off the FETs Q_1 , Q_2 and Q_4 (step S70). In this case, no current flows through the motor M.

When the polarities of the signal V, indicating the target motor voltage and the previous motor driving voltage Vs in the previous sampling cycle are matched (step S58), that is, for example, when the steoring wheel is being returned and the driving loces of the motor M is neither too much nor too little, the FET driving circuit 10 makes the current driving voltage Vs, zero, and turns off the FETs Q1, Q2, Q3 and Q4 (step S70). In this case, no current flows through the motor M.

In the subsequent sampling cycle, the signal processor 11 replaces the current motor driving voltage V_a with the previous motor driving voltage V_a with the previous motor driving voltage V_a test pS 73, and then, performs the subsequent sampling for the next steering torque value, and compares the polarity of the signal I₁ being equivalent to the subsequent target motor current and that of the signal V₁ being equivalent to the subsequent target motor voltage (step SSO). In this manner, such a procedure is repeated until the ignition switch (not shown) is turned of the subsequent target motor voltage (step SSO).

As described above, in returning the steering wheel to its neutral position, the only factor to generate a braking force in the reverse direction of the direction in which the steering wheel is returned is a generated current caused by the driving of the motor M flowing under the PWM control. Accordingly, the steering wheel can be returned smoothly. Further, neither a control hunting nor an abnormal noise in the motor M is caused.

Now, a motor lock check circuit in the electric power steering apperatus will be described. FIG. 9 is a block diagram showing the configuration in the major part of the motor lock check circuit. FETS Q1, Q2, Q3 and Q1, form a bridge circuit, and a motor M and a resistance R for detecting a motor driving current are connected in series so as to bridge the contact between the FETS Q1 and Q2, connected in series and the contact between the FETS Q2 and Q2 connected in series. The FETS Q1, Q2, Q3 and Q3 are connected with free wheeling clindes D1, D2, D3 and D3 in parallel, respontively. Further, the bridge circuit and if all safe relay 24 and a power supply B are connected in series.

After an ignition switch (not shown) is turned on, the fail safe relay 24 is turned on. In an off condition of an electromagnetic clutch (not shown) for transferring the driving force of the motor M to a steering assisting mechanism, an FET driving circuit 20 tums on, for example, the FETs Q1 and Q₄ to drive the motor M for a predetermined period of time. Then, the FET driving circuit 20 turns off the FETs Q1 and Q4, and simultaneously turns on the FET Qo. At this point, a generated voltage is caused by the inertial rotation of the motor M, and a regenerated current caused by the generated voltage flows through the free wheeling diode D1 and the FET Q₂. A motor current detecting circuit 21, which is conventionally provided for controlling a motor current, detects the regenerated current caused by the generated voltage from the voltages at both the ends of the resistance R. The motor M is stopped by being braked by the regenerated current caused by the generated voltage.

The operation of the motor lock check circuit in the electric power steering apparatus having the aforementioned configuration will be described referring to a flow chart shown in FIG. 10.

After the ignition switch is turned on, the fall safe rolay 24 is turned on (step S80). Then, in an off condition of the electromagnetic clutch (not shown) for transferring the driving force of the motor M to the steering assisting mechanism, a signal processor 27 turns on, for example, the FETs Q1 and Qa via the FET driving circuit 20, thereby driving the motor M by using a driving current flowing in the direction as shown with a solid line army 25 (step S81).

When a predetermined period of time has peased (step S82), the signal processor 27 sets a motor driving end flag (step S83), turns off the FET o. At this point, a generated voltage is caused by the inertial rotation of the motor M. and a regenerated current caused by the generated voltage flows in the motor M through the free wheeling diode op, and the FET O₂. The motor M is braked by this regenerated current (step S84).

The motor current detecting circuit 21 detects the regenerated current caused by the generated voltage of the motor M from the voltages at both ends of the resistance R. When the current exceeds a predetermined value (step SSS), the signal processor 27 sets a motor lock check OK flag (step SSB). After a predetermined motor braking time has passed (step S87), the motor lock check is terminated before the clutch is turned on.

When the current detected by the motor current detecting circuit 21 from the voltages at both ends of the resistance R does not exceed the

predetermined value (step \$85), after the predetermined motor braking time has passed (step \$88), the signal processor 27 sets a motor lock check NG flag (step \$89). Then, the signal processor 27 outputs an alarm signal indicating the faiture of the power steering apparatus to an alarm device (not shown) including an indicator light and the like (step \$90).

FIG. 11 is a timing chart showing the variation in the motor current during such a motor lock check. In this timing chart, T₁ indicates a driving time of the motor M₂, when a driving current flows in the direction as shown with the solid line arrow 25, and T₃ indicates a braking time of the motor M₂, when a regenerated current flows in the direction as shown with the broken line arrow 26.

As described above, according to the present electric power steering apparatus, the moor current detecting power steering apparatus, the moor current detecting circuit 21, which is conventionally provided for controlling a motor current, is used in operform the motor lock check. Therefore, a conventionally used motor terminal voltage detecting circuit 22 is not required, resulting in decreasing the producing cost. Further, there is no need for the motor Quarter of the motor M, which is conventionally required as shown in Fig. 4. Accordingly, the motor lock check requires a shorter period of time.

As this Invention may be embodied in several forms without departing from the spirit of essential characteristics thereof, the present embodiment is therefore illustrative and not restrictive, since the scope of the invention is defined by the appended claims rather than by the description preceding them, and all changes that fall within metes and bounds of the claims, or equivalence of such metes and bounds thereof are therefore intended to be embraced by the claims.

Claims

An electric power steering apparatus for assisting a steering force by driving a motor (M) so as to decrease torque supplied to a steering wheel, comprising a bridge circuit including said motor (M) and two pairs of first and second switching elements (Q₁, Q₂, Q₃ and Q₄), said two pairs being provided for driving said motor in the clockwise direction and in the counterclockwise direction, respectively, characterized by inclusion:

decision means for deciding whether said steering wheel is being returned to its neutral position; and

means (10) for performing PWM control on one of said first switching elements in accordance with the torque supplied to said steering wheel and turning off one of said second switching elements belonging to the same pair as said first switching element belongs to, when said decision means decides that said steering wheel is being returned to its neutral position.

 An electric power steering apparatus according to claim 1, wherein said decision means includes:

a resistance (R) connected in series with said motor at a bridging portion in said bridge circuit:

a differential amplifier (1) for obtaining a difference between a motor driving current detected by sald resistance and a target value of the motor driving current in accordance with the torque supplied to said steering wheel;

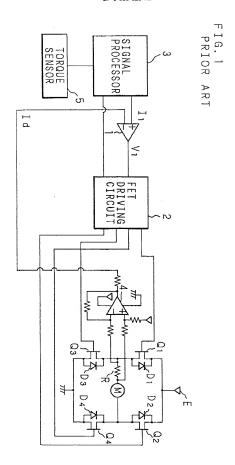

means (11) for deciding whether polarities of said target value of the motor driving current and a differential output of said differential amplifier (1) are different; and

means (10) for detecting change of the polarity of said differential output, and

said decision means decides that said steering wheel is being returned to its neutral position when said means (11) for deciding whether the polarities are different decides that he polarities are different and said means (10) for detecting the change of the polarity decides that the polarity is changed.

 An electric power steering apparatus according to claim 1, wherein said means (10) for performing PVM control usually performs PVM control on said second switching element in accordance with the torque supplied to said steering wheel and turns on said first switching element.
